

Distributed Query Processing

Distributed Query Processing

- For centralized systems, the primary criterion for measuring the cost of a particular strategy is the number of disk accesses.
- In a distributed system, other issues must be taken into account:
 - The cost of a data transmission over the network.
 - The potential gain in performance from having several sites process parts of the query in parallel.

Query Transformation

- Translating algebraic queries on fragments.
 - It must be possible to construct relation r from its fragments
 - Replace relation r by the expression to construct relation r from its fragments
- Consider the horizontal fragmentation of the account relation into

```
account_1 = \sigma_{branch\_name} = "Hillside" (account)

account_2 = \sigma_{branch\_name} = "Valleyview" (account)
```

■ The query σ _{branch name = "Hillside"} (account) becomes

```
\sigma branch_name = "Hillside" (account_1 \cup account_2) which is optimized into
```

```
\sigma branch_name = "Hillside" (account<sub>1</sub>) \cup \sigma branch_name = "Hillside" (account<sub>2</sub>)
```

Example Query (Cont.)

- Since account₁ has only tuples pertaining to the Hillside branch, we can eliminate the selection operation.
- Apply the definition of $account_2$ to obtain $\sigma_{branch_name} = \text{"Hillside"} (\sigma_{branch_name} = \text{"Valleyview"} (account)$
- This expression is the empty set regardless of the contents of the account relation.
- Final strategy is for the Hillside site to return account₁ as the result of the query.

Simple Join Processing

- Consider the following relational algebra expression in which the three relations are neither replicated nor fragmented account ⋈ depositor ⋈ branch
- account is stored at site S₁
- \blacksquare depositor at S_2
- branch at S_3
- For a query issued at site S_1 , the system needs to produce the result at site S_1

Possible Query Processing Strategies

- Ship copies of all three relations to site S_1 and choose a strategy for processing the entire locally at site S_1
- Ship a copy of the account relation to site S_2 and compute $temp_1 = account \bowtie depositor at S_2$. Ship $temp_1$ from S_2 to S_3 , and compute $temp_2 = temp_1$ branch at S_3 . Ship the result $temp_2$ to S_1 .
- Devise similar strategies, exchanging the roles S_1 , S_2 , S_3
- Must consider following factors:
 - amount of data being shipped
 - cost of transmitting a data block between sites
 - relative processing speed at each site

Semijoin Strategy

- Let r_1 be a relation with schema R_1 stores at site S_1 Let r_2 be a relation with schema R_2 stores at site S_2
- Evaluate the expression $r_1 \bowtie r_2$ and obtain the result at S_1 .
- 1. Compute $temp_1 \leftarrow \prod_{R1 \cap R2} (r1)$ at S1.
- 2. Ship $temp_1$ from S_1 to S_2 .
- 3. Compute temp₂ ← r_{2 ⋈} temp1 at S₂
- 4. Ship temp₂ from S₂ to S₁.
- 5. Compute $r_1 \bowtie temp_2$ at S_1 . This is the same as $r_1 \bowtie r_2$.

Formal Definition

■ The **semijoin** of r_1 with r_2 , is denoted by:

$$r_1 > < r_2$$

it is defined by:

$$\prod_{R_1} (r_1 \bowtie r_2)$$

- Thus, $r_1 \bowtie r_2$ selects those tuples of r_1 that contributed to $r_1 \bowtie r_2$.
- In step 3 above, $temp_2 = r_2 \bowtie r_1$.
- For joins of several relations, the above strategy can be extended to a series of semijoin steps.

Join Strategies that Exploit Parallelism

- Consider $r_1 \bowtie r_2 \bowtie r_3 \bowtie r_4$ where relation r_i is stored at site S_i . The result must be presented at site S_1 .
- r_1 is shipped to S_2 and $r_1 \bowtie r_2$ is computed at S_2 : simultaneously r_3 is shipped to S_4 and $r_3 \bowtie r_4$ is computed at S_4
- S₂ ships tuples of $(r_1 \bowtie r_2)$ to S₁ as they produced; S₄ ships tuples of $(r_3 \bowtie r_4)$ to S₁
- Once tuples of $(r_1 \bowtie r_2)$ and $(r_3 \bowtie r_4)$ arrive at S_1 $(r_1 \bowtie r_2) \bowtie (r_3 \bowtie r_4)$ is computed in parallel with the computation of $(r_1 \bowtie r_2)$ at S_2 and the computation of $(r_3 \bowtie r_4)$ at S_4 .

Heterogeneous Distributed Databases

- Many database applications require data from a variety of preexisting databases located in a heterogeneous collection of hardware and software platforms
- Data models may differ (hierarchical, relational, etc.)
- Transaction commit protocols may be incompatible
- Concurrency control may be based on different techniques (locking, timestamping, etc.)
- System-level details almost certainly are totally incompatible.
- A multidatabase system is a software layer on top of existing database systems, which is designed to manipulate information in heterogeneous databases
 - Creates an illusion of logical database integration without any physical database integration

Advantages

- Preservation of investment in existing
 - hardware
 - system software
 - Applications
- Local autonomy and administrative control
- Allows use of special-purpose DBMSs
- Step towards a unified homogeneous DBMS
 - Full integration into a homogeneous DBMS faces
 - Technical difficulties and cost of conversion
 - Organizational/political difficulties
 - Organizations do not want to give up control on their data
 - Local databases wish to retain a great deal of autonomy

Unified View of Data

- Agreement on a common data model
 - Typically the relational model
- Agreement on a common conceptual schema
 - Different names for same relation/attribute
 - Same relation/attribute name means different things
- Agreement on a single representation of shared data
 - E.g. data types, precision,
 - Character sets
 - ASCII vs EBCDIC
 - Sort order variations
- Agreement on units of measure
- Variations in names
 - E.g. Köln vs Cologne, Mumbai vs Bombay

Query Processing

- Several issues in query processing in a heterogeneous database
- Schema translation
 - Write a wrapper for each data source to translate data to a global schema
 - Wrappers must also translate updates on global schema to updates on local schema
- Limited query capabilities
 - Some data sources allow only restricted forms of selections
 - ▶ E.g. web forms, flat file data sources
 - Queries have to be broken up and processed partly at the source and partly at a different site
- Removal of duplicate information when sites have overlapping information
 - Decide which sites to execute query
- Global query optimization

Mediator Systems

- Mediator systems are systems that integrate multiple heterogeneous data sources by providing an integrated global view, and providing query facilities on global view
 - Unlike full fledged multidatabase systems, mediators generally do not bother about transaction processing
 - But the terms mediator and multidatabase are sometimes used interchangeably
 - The term virtual database is also used to refer to mediator/multidatabase systems

Transaction Management in Multidatabases

- Local transactions are executed by each local DBMS, outside of the MDBS system control.
- Global transactions are executed under multidatabase control.
- Local autonomy local DBMSs cannot communicate directly to synchronize global transaction execution and the multidatabase has no control over local transaction execution.
 - local concurrency control scheme needed to ensure that DBMS's schedule is serializable
 - in case of locking, DBMS must be able to guard against local deadlocks.
 - need additional mechanisms to ensure global serializability

Local vs. Global Serializability

- The guarantee of local serializability is not sufficient to ensure global serializability.
 - As an illustration, consider two global transactions T1 and T2, each of which accesses and updates two data items, A and B, located at sites S1 and S2 respectively.
 - It is possible to have a situation where, at site S1, T2 follows T1, whereas, at S2, T1 follows T2, resulting in a nonserializable global schedule.
- If the local systems permit control of locking behavior and all systems follow two-phase locking
 - the multidatabase system can ensure that global transactions lock in a two-phase manner
 - the lock points of conflicting transactions would then define their global serialization order.
